On the Capacity of Computer Memory with Defects

CHRIS HEEGARD, MEMBER, IEEE, AND ABBAS A. EL GAMAL, MEMBER, IEEE

Abstract—A computer memory with defects is modeled as a discrete memoryless channel with states that are statistically determined. The storage capacity is found when complete defect information is given to the encoder or to the decoder, and when the defect information is given completely to the decoder but only partially to the encoder. Achievable storage rates are established when partial defect information is provided at varying rates to both the encoder and the decoder. Arimoto-Blahut type algorithms are used to compute the storage capacity.

I. INTRODUCTION

We model a computer memory with defects and noise as a discrete memoryless channel with states that are statistically determined [1]. For example, a binary memory with stuck-at faults and soft errors is modeled by the three discrete memoryless channels depicted in Fig. 1. Each memory cell has probability $p/2$ of being stuck at 0, probability $p/2$ of being stuck at 1, and probability $1 - p$ of behaving as a binary symmetric channel (BSC) with parameter $\epsilon$.

If neither the decoder nor the encoder knows the states of the memory the defects act as binary symmetric noise and the storage capacity of the memory (i.e., the maximum number of bits that can be reliably stored) is simply given by

$$C_{\max} = (1 - p)(1 - h(\epsilon)) \text{ bits/cell,}$$

where

$$h(x) = -x \log(x) - (1-x) \log(1-x).$$

On the other hand, if both the encoder and the decoder know the states of the memory the storage capacity can be easily shown to be

$$C_{\min} = 1 - h((1 - p)\epsilon + \frac{p}{2}) \text{ bits/cell.}$$

IEEE TRANSACTIONS ON INFORMATION THEORY, VOL. IT - 29, NO. 5, SEPTEMBER 1983 731
When only the decoder knows the states of memory, the stuck-at cells can be treated as erasures, and the memory model reduces to a noisy binary erasure channel with erasure probability \( p \) and error probability \( (1 - p) \). The storage capacity, in this case, is again given by (1.2).

Suppose only the encoder is given the defect information. The following argument shows that the capacity is again given by (1.2). Choose a set of \( 2^n R \) Bernoulli 1/2 binary sequences for some \( R < 1 - h(e) \). With high probability this set will be a good code for the BSC with parameter \( e \). Randomly partition the set into \( 2^n R \) equal size subsets (or bins) and associate a different message with each bin. When the \( i \)th message is to be stored, search the \( i \)th bin for a sequence that is compatible with the known defect. (A sequence is compatible with the defect if it agrees with the stuck-at values in a fraction \( 1 - \epsilon \) of these cells.) If an \( e \)-compatible sequence is found in the \( i \)th bin it is stored, otherwise an error is declared. This codeword will now be correctly decoded with high probability, since each bit will experience an error with probability \( e \). For large \( n \) there will be approximately \( np \) stuck bits, thus there are approximately \( 2^{n(1-p+pe)} \) binary sequences that are \( e \)-compatible with a given defect. The probability that an \( e \)-compatible sequence is in the code is \( 2^{n(R-1)} \), thus the expected number of \( e \)-compatible sequences in the code book is the product \( 2^{n(R-p+pe)} \). If the number of bins is much smaller than the number of \( e \)-compatible sequences, then with high probability there will be an \( e \)-compatible sequence in the \( i \)th bin. This is true for \( R < R' - p + ph(e) \) and sufficiently large \( n \). Since \( R' \) can be made arbitrarily close to \( 1 - h(e) \) we see that the capacity is given by (1.2).

Observe that for the case \( \epsilon = 0 \), the storage capacity is given by

\[
C = (1 - p) \text{ bits/cell.}
\]

This is consistent with the work of Kusnetsov and Tsybakov [2]. Their work initiated a series of papers [3]-[8] concerning classes of binary codes for the case when the lower bound is tight in the following special cases (Theo-

In Section II, we give a general lower bound (Theo-

This lower bound is tight in the following special cases (Theo-

In this paper we investigate the problem of finding the storage capacity of a memory with arbitrary but finite storage and retrieval alphabets and arbitrary collection of states. In Section II, we give a general lower bound (Theo-

In this state, if the letter \( x \in X \) is stored in the \( i \)th bin it

This is the probability that for a random message (and

The map \( J_e \) provides a description of the state vector \( s \) for the encoder \( f_e \) at a rate of \( R_e \) bits/cell. The map \( J_d \) provides a similar service for the decoder \( f_d \) at a rate of \( R_d \) bits/cell. The encoder maps the message \( w \) and the state description \( J_e \) into an input vector \( x \). Finally, the decoder maps the output sequence \( y \) and the \( J_d \) description into an estimate of the message \( \hat{w} \).

The probability of error is defined as

\[
P_e = 2^{-n R} \sum_{w=1}^{2^n R} P(\hat{w} = w | w \text{ is stored})
\]

\[
= 2^{-n R} \sum_{w=1}^{2^n R} \sum_{x \in X^w} \sum_{y \in Y^w} p(s) p(f_d(y, J_d) = w | x = f_e(w, J_e), s).
\]

This is the probability that for a random message (and memory), the estimated message disagrees with the true message.

For a fixed \( R_e \) and \( R_d \), a rate triple \( (R, R_e, R_d) \) is achievable if and only if for any \( \epsilon > 0 \) there exists a
HEEGARD AND EL GAMAL: CAPACITY OF COMPUTER MEMORY

\[(n, R, R_e, R_d, P_e)\] code with \(P_e < \epsilon\) for some (possibly large) \(n\). The capacity function \(C(R_e, R_d)\) of the memory is defined as the supremum over all achievable rates \(R\) for fixed \((R_e, R_d)\). We define the following four special values of \(C(R_e, R_d)\):

\[
\begin{align*}
    C_{\text{max}} &= \sup_{R_e, R_d} C(R_e, R_d), \\
    C_{\text{min}} &= \inf_{R_e, R_d} C(R_e, R_d), \\
    C_{\text{enc}} &= \sup_{R_e} C(R_e, 0), \\
    C_{\text{dec}} &= \sup_{R_d} C(0, R_d).
\end{align*}
\]

It can easily be seen that \(C_{\text{max}}\) is the capacity when full knowledge of the states is given to both the encoder and decoder. Similarly, \(C_{\text{min}}\) is the capacity when no state information is provided, \(C_{\text{enc}}\) is the capacity when only the encoder is given full information about the states, and \(C_{\text{dec}}\) is the capacity when full state information is given only to the decoder.

We would hope to find an explicit characterization of \((R_e, R_d)\) for all rates \((R_e, R_d)\). The complete solution to this problem has not been found. However, the following theorem gives lower bounds to \(C(R_e, R_d)\) by describing a set of achievable rates \((R_e, R_d)\).

**Theorem 1:** Fix \((S, p(s), X, p(y|x, s), Y)\) and alphabets \(U, S_0, S_e, S_d\). All rates \((R_e, R_d)\) in the convex hull of the set

\[
\begin{align*}
    (R_e, R_d) &> I(S_0, S_e; S) \\
    R_e &> I(S_0, S_e; S) - I(S_0, S_d; Y) \\
    R_d &> I(S_0, S_d; Y) - I(S_0, S_d; S) \\
    R_e + R_d &> I(S_0, S_d, S_e; S) - I(S_0, S_d; Y) + I(S_e; S_d|S_0) \\
    R_e + R_d &> I(S_0, S_d, S_e; S) - I(S_0, S_d; Y) + I(S_e; S_d|S_0) \\
    K &< I(U; Y, S_d|S_0) - I(U; S_d|S_0)
\end{align*}
\]

for some probability mass function

\[p(s, s_0, s_e, s_d, u, x) = p(s)p(s_0, s_e, s_d|s)p(u|x|s_0, s_e)\]

are achievable.

The proof of Theorem 1 involves techniques similar to those found in \([14]-[16], [19], [20]\) and is therefore deferred to Appendix I.

**Remark:** If we let \(R_e = 0\), Theorem 1 reduces to the convex hull of the set

\[
\begin{align*}
    (R, R_d) &> I(S_d; Y); R < I(X, Y|S_d), \\
    &\text{for some probability mass function} \\
    p(s, s_d, x) &= p(s)p(s_d|x)p(x).
\end{align*}
\]

This result is identical to a result by Ahlswede and Han [13].

We now show that for several values of \((R_e, R_d)\), Theorem 1 is optimal. These include \(C_{\text{min}}, C_{\text{max}}, C_{\text{enc}},\) and \(C_{\text{dec}}\).

**Theorem 2:** a) \(R_e = R_d = 0\) (No description of defects)

\[C_{\text{min}} = \max_{p(x)} I(X; Y).\]

b) \(R_e > H(S), R_d > H(S|Y)\) (Complete description of defects at encoder and decoder)

\[C_{\text{max}} = \max_{p(x)} I(X; Y|S).\]

c) \(R_e > H(S), R_d = 0\) (Complete description of defects at encoder and no description at decoder)

\[C_{\text{enc}} = \max_{p(u, x|s)} I(U; Y) - I(U; S),\]

where

\[\|U\| \leq \min (\|X\|, \|Y\|) + \|S\| - 1.\]

d) \(R_d > H(S|Y)\) (Complete description of defects at decoder)

\[C_{\text{dec}} = \max_{p(x)} I(X; Y|S).\]

Furthermore, in the special case \(R_e = 0\):

\[C_{\text{dec}} = \max_{p(x)} I(X; Y|S).\]

The achievability of this theorem follows from Theorem 1 by identifying the auxiliary random variables as follows:

- a) \(S_0 = S_e = S_d = \emptyset, U = X;\)
- b) \(S_0 = S_e = S_d = \emptyset, U = X;\)
- c) \(S_0 = S_d = \emptyset, S_e = S;\) and
- d) \(S_e = \emptyset, (S_0, S_d) = S, U = X.\)

The converses are proved in Appendix II.

The following corollary to Theorem 2 concerns the capacity of a memory with stuck-at type defects.

**Corollary:** Let \(S = \{1, 2, \ldots, m\}, p(y|x, s = 1)\) be arbitrary and for \(i > 1\) let \(p(y|x, s = i) = 1\) for some \(y_i \in Y\). Then

\[C_{\text{max}} = C_{\text{enc}} = C_{\text{dec}} = p(s = 1)C,\]

where \(C\) is the capacity of the DMC with \(p(y|x) = p(y|x, s = 1).\)

**Proof:** Let \(p^*(x)\) be a probability mass function on \(X\) which achieves capacity for the DMC \((X, p(y|x, s = 1), y)\), and let \(p^*(x|y)\) be the (backward) probability transition matrix for the DMC induced by \(p^*(x)\). To achieve \(C_{\text{dec}}, \text{set } p(x) = p^*(x).\) To achieve \(C_{\text{enc}}, \text{set } U = X, \text{p}^*(x|s = 1) = p^*(x|y), \text{and for } i > 1 \text{ set } p(x|s = i) = p^*(x|y_i).\)

This corollary shows that for memories which have only stuck-at type defects, \(C_{\text{max}}\) can be achieved by providing the full defect information to only the encoder or only to the decoder. We also note that \(C_{\text{max}} = C_{\text{dec}} = p(s = 1)C\) if \(i > 1\) \(Y\) is independent of \(X\) (i.e., \(p(y|x, s = i) = p(y|x)\)). In this case, it need not be true that \(C_{\text{enc}} = C_{\text{max}}\), as some of the examples in the following section will demonstrate.

**III. ALGORITHMS AND EXAMPLES**

Determining \(C_{\text{min}}, C_{\text{max}}, C_{\text{enc}},\) and \(C_{\text{dec}}\) for an arbitrary DMMC can be a difficult analytical problem. However,
these quantities can be easily evaluated numerically on a computer. The Arimoto-Blahut [10]-[12] algorithm maximizes \( I(X; Z) \) over \( p(x) \) for a given transition probability \( p(z|x) \). This algorithm can be used to compute \( C_{\text{min}}, C_{\text{max}}, \) and \( C_{\text{dec}} \).

The value of \( C_{\text{min}} \) can be computed by setting \( Z = Y \) and maximizing \( I(X; Z) \) for

\[
P(Z = y|x) = \sum_{s \in S} p(s) p(y|x, s).
\]

The value of \( C_{\text{max}} \) can be determined by setting \( Z = Y \) for each \( s \in S \) and maximizing \( I(X; Z) = I(X; Y|s) \) for \( P(Z = y|x) = p(y|x, s) \). Then we average the results of each maximization

\[
I(X; Y|s) = \sum_{s \in S} p(s) I(X; Y|s).
\]

To compute \( C_{\text{dec}} \), we use the Arimoto-Blahut (A-B) algorithm with \( Z = (Y, S) \). We maximize \( I(X; Z) = I(X; Y, S) \) with

\[
P(Z = (y, s)|x) = p(s) p(y|x, s).
\]

The result of this maximization is \( C_{\text{dec}} = I(X; Y|S) \) since \( X \) and \( S \) are independent (i.e., \( I(X; S) = 0 \)).

The value of \( C_{\text{enc}} \) cannot be computed directly by the A-B algorithm. A new algorithm is developed to compute \( C_{\text{enc}} \). This algorithm is presented here. The detailed derivation is given in Appendix III.

To compute \( C_{\text{enc}} \), we express the capacity as

\[
C_{\text{enc}} = \max_{q'} \max_{q} \max_{Q} F(q', q, Q),
\]

where

\[
F = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p(s) q(u|s) q'(x|u, s) p(y|x, s) \cdot p(y|x, s) \log \frac{Q(u|y)}{q(u|s)}.
\]

The parameters \( q(u|s), Q(u|y) \) are conditional probability mass functions on the alphabet \( U \), and \( q'(x|u, s) \) is a conditional probability mass function on the alphabet \( X \).

A flowchart describing the algorithm is given in Fig. 3.

Initially, \( q(u|s) \) is set equal to an arbitrary positive transition matrix (e.g., \( q(u|s) = 1/|U| \)) and \( q'(x|u, s) \) is set equal to an arbitrary zero–one transition matrix. The main iteration cycles through each of the three arguments increasing \( F \) with respect to one argument while leaving the other two fixed.

\( F \) is maximized over \( Q \) for fixed \( q \) and \( q' \) by setting \( Q(u|y) \) equal to the conditional probability of \( u \) given \( y \)

\[
Q(u|y) = \frac{\sum_{s \in S} \sum_{x \in X} p(s) q(u|s) q'(x|u, s) p(y|x, s)}{\sum_{u \in U} \sum_{s \in S} \sum_{x \in X} p(s) q(u|s) q'(x|u, s) p(y|x, s)}. \tag{3.1}
\]

For this value of \( Q \), \( F = I(U; Y) - I(U; S) \).

To maximize \( F \) with respect to \( q' \) we set \( q'(x|u, s) = 1 \) for an \( x \in X \) which maximizes

\[
Q(u|y) - Q(u|s) \cdot \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p(s) q(u|s) q'(x|u, s) p(y|x, s) \cdot \log \left( \frac{Q_0(u|y)}{q(u|s)} \right),
\]

for each \( u \in U \) and \( s \in S \).

This implies that we can always assume that \( x \) is a deterministic function of \( u \) and \( s \) without loss of capacity. We define

\[
A(q, Q) = (q'|q' \text{ is a 0–1 matrix which maximizes } F).
\]

Finally, \( F \) is maximized over \( q \) by

\[
q(u|s) = \frac{\prod_{y \in Y} Q(u|y) q(x|u, s)p(y|x, s)}{\sum_{u \in U} \prod_{y \in Y} Q(u|y)^{q(x|u, s)p(y|x, s)}}.
\]

For fixed \( q' \)

\[
U(q', q) = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} p(y|x, s) \cdot \log \left( \frac{Q_0(u|y)}{q(u|s)} \right),
\]

(3.1) forms an upper bound on \( F(q', q, Q) \) which converges to \( F \) as \( F \) approaches a maximum. The algorithm terminates with \( |C_{\text{enc}} - F| < \epsilon \), for any desired accuracy \( \epsilon > 0 \).

We now discuss three examples of a memory with defects. The first example is an extension of the simple example discussed in the introduction. For this example, it is found that \( C_{\text{enc}} \leq C_{\text{dec}} \leq C_{\text{max}} \). The second example con-
Example 1: (Binary Cell with defects and symmetric noise) The memory cell model is depicted in Fig. 4. In Fig. 5, plots are given of $C_{\min}$, $C_{\max}$, $C_{\text{enc}}$, and $C_{\text{dec}}$. We note that the only capacity that varies with the parameter $\alpha$ is $C_{\min}$ and that only $C_{\text{enc}}$ depends on the parameter $\beta$.

Example 2: (Two Binary Symmetric Channels (Fig. 6)) In Fig. 7, we give plots of $C_{\min}$, $C_{\max}$, $C_{\text{enc}}$, and $C_{\text{dec}}$. If $\epsilon_1$ and $\epsilon_2$ are both less than $1/2$, then $C_{\min} = C_{\text{enc}} \leq C_{\text{dec}} = C_{\max}$. However, if $\epsilon_1 < 1/2$ and $\epsilon_2 > 1/2$, then the encoder can achieve rates higher than $C_{\min}$ by complementing the input on the $s = 2$ cells.

Example 3: The example depicted in Fig. 8 shows that there are cases where $C_{\text{dec}} < C_{\text{enc}}$. For this example, $C_{\min} = 0$, $C_{\text{dec}} = 2/3$, and $C_{\text{enc}} = C_{\max} = 1$ bit/cell.

IV. Conclusion

We have seen that the storage capacity of a computer memory can be improved by providing the encoder or the decoder with information about the permanent defects. When the encoder or decoder is provided with an exact description of the locations and nature of all defects we have established the capacity. However, except for the case pertaining to part d) of Theorem 2, the storage capacity of the memory with a partial description of the defects is still an open problem.

Acknowledgment

The authors are thankful to Thomas Cover for the many valuable suggestions he has made to improve this paper. We also thank Dave Gluss and Max Costa for their help. Thanks are also due to Te Sun Han for his valuable comments on Appendix I.
APPENDIX I:
PROOF OF THEOREM 1

The outline consists of three parts. For this discussion, we fix $\epsilon > 0$, alphabetes $U, S_i, S_j, S_k$ and joint distribution

$$p(s, s_0, s_d) = p(s) p(s_0, s_d | s) p(u, x | s) p(y | x, s).$$

The first part concerns the existence of three maps $g_0 : S^n \rightarrow S'_0$, $g_1 : S^n \rightarrow S'_1$, $g_2 : S^n \rightarrow S'_2$ such that if

$$R_0 \triangleq \frac{1}{n} \log \|g_0\| > I(S_0; S) + 3\delta$$

$$R_1 \triangleq \frac{1}{n} \log \|g_1\| > R_0 + I(S_0; S | S_0) + 4\delta$$

$$R_2 \triangleq \frac{1}{n} \log \|g_2\| > R_0 + I(S_0; S | S_0) + 4\delta$$

$$R_1 + R_2 > R_0 + I(S_0, S_0; S | S_0) + I(S_1; S_1 | S_0) + 6\delta$$

and $n$ is sufficiently large, then

$$P((g_0(S), g_1(S), g_2(S), S) \in T(S_0, S_0, S_0, S_0)) > 1 - \epsilon.$$  

(A2)

Note that $\|g_i\|$ is cardinality of the range of $g_i$ and $R(\epsilon) > 0$ is defined such that $\delta \rightarrow 0$ as $\epsilon \rightarrow 0$. (See [17] for a discussion of jointly typical sets $T(\cdot, \cdot)$.)

The proof of this result follows by showing that on the average the following construction obtains the desired maps [14], [15]. Choose independently a set of vectors $(S'_0)_{i, j} = 1 \leq i \leq 2^n R_0$ according to a uniform distribution over the set $T(S_0)$. For each $1 \leq i < 2^n R_0$, independently choose two sets of vectors $(S'_1)_{i, j} = 1 \leq j \leq 2^n R_1 - R_0$ and $(S'_2)_{i, k} = 1 \leq k \leq 2^n R_2 - R_0$ according to a uniform distribution over the sets $T(S, S_0)$ and $T(S, S_1)$, respectively. For each $s \in T(S)$ look for an $1 \leq i \leq 2^n R_0$, $1 \leq j \leq 2^n R_1 - R_0$ and $1 \leq k \leq 2^n R_2 - R_0$ with $(S'_0), (S'_1), (S'_2)$ in $T_i(S_0, S_0, S_0)$, $T_j(S_0, S_1, S_0)$ and $T_k(S_0, S_0, S_1)$. Set $g_0(s) = S'_0$, $g_1(s) = S'_1$, and $g_2(s) = S'_2$. For any $s \in T(S)$ or if we cannot find such a triple, set $g_0(s) = S'_1$, $g_1(s) = S'_1$, and $g_2(s) = S'_1$. With this construction, if $S$ is drawn according to $P(S = s) = \Pi_{i=1}^{n-1} p(s_i)$ and (A1) is satisfied then (A2) will follow for sufficiently large $n$.

The second part of the proof concerns the existence of two maps $f_0 : S'_0 \times S'_0 \rightarrow (1, 2^n R)$ and

$$f_0 : S'_0 \times S'_0 \rightarrow (1, 2^n R)$$

that can be used to label the ranges of three maps $g_0, g_1,$ and $g_2$ constructed in part 1 of the proof. Specifically we argue that for sufficiently large $n$, when

$$R_2 > R_1$$

$$R_1 > \max \left( R_2 - I(S_0, S_0; Y), R_2 - R_0 - I(S_0; Y | S_0) \right)$$

then given $J_2(g_0(S), g_1(S))$ we can find an estimate $(\hat{S}_0, \hat{S}_0)$ with

$$P\left( (\hat{S}_0, \hat{S}_0) = (g_0(S), g_1(S)) \right) > 1 - \epsilon$$

(A4)

and given $J_2(g_0(S), g_2(S))$ and the output vector $Y$ we can find an estimate $(\hat{S}_0, \hat{S}_2)$ with

$$P\left( (\hat{S}_0, \hat{S}_2) = (g_0(S), g_2(S)) \right) > 1 - \epsilon.$$  

(A5)

The first map $f_0$ can be easily disposed of by recognizing that $\|g_0, g_1\| = \|g_0\| = 2^n R_0$. The existence of the second map $f_0$ follows by averaging the following random construction [17], [19], [20]. For each unique pair $(g_0(s), g_2(s))$ independently choose $J_2(g_0(s), g_2(s))$ according to a uniform distribution over the set of integers $(1, 2^n R)$. Let $(A_3)$ be satisfied and choose $(S, Y)$ according to the distribution $\Pi_{i=1}^{n-1} p(x_i, y_i)$. Given $J_2(g_0(S), g_2(S))$ and $Y$ choose the estimate $(\hat{S}_0, \hat{S}_2)$ as any pair $(g_0(s), g_2(s)) \in T_c(S_0, S_2)$ with $J_2(g_0(s), g_2(s)) = J_2(g_0(S), g_2(S))$. Then if $n$ is sufficiently large, (A5) will follow. By combining (A1) and (A3) we arrive at the desired bounds

$$R_0 > I(S_0; S_0; S_2) + 7\delta$$

$$R_1 > \max \left( I(S_0, S_0; S_2; Y) - I(S_0; Y | S_0) + 10\delta, 0 \right)$$

$$R_2 > \max \left( I(S_0; Y | S_0) + I(S_2; S_2 | S_0) + 12\delta, 0 \right)$$

such that when

$$R \leq I(U; Y, S_2 | S_0) - I(U; S_0 | S_0) - 98$$

and $n$ is sufficiently large than for a random message $W \in (1, 2^n R)$

$$P((f_0(Y, \hat{S}_0, \hat{S}_2) = W | X = f_0(W, \hat{S}_0, \hat{S}_2)) > 1 - \epsilon.$$  

(A7)

The following random construction will prove the existence of these maps. Let $R, R'$ satisfy

$$I(U; S_0 | S_0) + 48 < R' < I(U; S_0 | S_0) + 58$$

$$R + R' < I(U; S_0, Y | S_0) - 48.$$  

(A8)

For each $s_0 \in T(S_0)$, $1 \leq i \leq 2^n R_0$ and $1 \leq w \leq 2^n R_0$ independently choose a vector $U^i_{w} \in \Pi_{i=1}^{n-1} p(s_i)$ and (A1) is satisfied then (A2) will follow for sufficiently large $n$.

The first part of the proof concerns the last inequality of the theorem. This portion concerns the existence of maps $f_c : (1, 2^n R) \times S'_0 \times S'_2 \rightarrow X^n$ such that when

$$R' \leq I(U; Y, S_2 | S_0) - I(U; S_0 | S_0) - 98$$

and $n$ is sufficiently large than for a random message $W \in (1, 2^n R)$

$$P((f_c(Y, \hat{S}_0, \hat{S}_2) = W | X = f_c(W, \hat{S}_0, \hat{S}_2)) > 1 - \epsilon.$$  

(A7)

The following random construction will prove the existence of these maps. Let $R, R'$ satisfy

$$I(U; S_0 | S_0) + 48 < R' < I(U; S_0 | S_0) + 58$$

$$R + R' < I(U; S_0, Y | S_0) - 48.$$  

(A8)

The achievability part of the theorem follows immediately by application of Theorem 1. The converse of the theorem is easily derived for parts a) and b) and has already been presented for

APPENDIX II:
PROOF OF THEOREM 2

The achievability part of the theorem follows immediately by application of Theorem 1. The converse of the theorem is easily derived for parts a) and b) and has already been presented for
part c) [9]. The converse for part d) is derived here. The proof shows that for any \((n, R, R_e, R_q, P_e)\) code with \(R_q > H(S|Y)\), there exists an \(\epsilon > 0\) and a random variable \(S_0\) such that \(S \rightarrow S_0 \rightarrow X\) as a Markov chain and

\[
R_e \geq I(S_0; S) \quad R < I(X; Y|S) + \epsilon. \quad (A9)
\]

Furthermore, \(\epsilon(P_e)\) is defined such that \(\epsilon \rightarrow 0\) as \(P_e \rightarrow 0\).

First we need prove that the region of all rate triples \((R, R_e, H(S|Y))\) achieved by Theorem 1 is convex in \((R, R_e)\) for fixed \(P_e(s), p(y|x, s)\). Let

\[
A = \{(R, R_e) | R_e > Z(S_0; S), R < Z(X; Y|S), \}
\]

and

\[
B = \{(R, R_e) | R_e > Z(S, S'| Z), R < Z(X; Y|S, Z), \}
\]

where

\[
p(s, s_0, x, y) = p(s) p(s_0|x, s) p(x|s_0, y)
\]

and

\[
\begin{align*}
Q(s, s_0, x, y) &= p(s) p(s_0|x, s) p(x|s_0, y) p(y|x, s), \\
R_s &= I(S_0; S) \quad (\text{independence}), \\
R_e &= I(S_0; Z|S) \quad R < I(X; Y|S, Z), \quad \text{leq} I(X; Y|S)
\end{align*}
\]

since \(I(Z; Y|X, S) = 0\). Thus \((R, R_e) \in A\) and convexity is proved.

The entropy of the message random variable is

\[
H(W) = \log |W| \leq nR
\]

by assumption. If we take

\[
\epsilon(P_e) = P_e R + \frac{1}{n} h(p_e),
\]

then we obtain the Fano's inequality

\[
H(W|Y, S) \leq n\epsilon. \quad (A10)
\]

Note \(\epsilon > 0\) and \(\epsilon \rightarrow 0\) as \(P_e \rightarrow 0\) as required.

Now, let \(J_e = J_e(S)\) be the encoder's description of the defect vector \(S\).

\[
nR_e \geq H(J_e) \geq I(J_e; S) = \sum_{i=1}^{n} I(J_e; S_i|S'_i) - \sum_{i=1}^{n} I(J_e; S_i'; S) \quad (\text{independence}), \quad (A11)
\]

where \(S_i' = S_i, S_i' = [S_{i+1}, S_{i+2}, \ldots, S_n]\). Then

\[
nR = H(W) = H(W|J_e, S) \quad \text{(independence)} \leq I(W; Y|J_e, S) + \epsilon \quad \text{leq from A10}
\]

\[
= \sum_{i=1}^{n} I(W; Y_i|J_e, S_i, S_i') + \epsilon
\]

where \(Y_i = \psi, Y_i' = [Y_1, Y_2, \ldots, Y_{i-1}]\)

\[
\leq \sum_{i=1}^{n} I(W, J_e, S_i, Y_i'|Y_i) + \epsilon
\]

\[
\leq \sum_{i=1}^{n} I(X_i; Y_i|S_i) + \epsilon
\]

since \(W, J_e, S_i', Y_i' \rightarrow X_i, S_i \rightarrow Y_i\) form a Markov chain.

Finally, since \(S_0, J_e, S_i', Y_i'\) form a Markov chain and by convexity of the achievable region, there exists a distribution \(p(s_0|x, p(x|s_0)\) such that (A11) and (A12) imply (A9).

APPENDIX III: DERIVATION OF ALGORITHM FOR \(C_{\text{conc}}\)

Fix \((S, p(s), X, p(y|x, s), Y), U\) and let

\[
p_0(s, u, x, y) = p(s) q(u|x, s) p(y|x, s)
\]

be a probability mass function on \(S \times U \times X \times Y\). Then

\[
Q_0(u|y) = \sum_{s \in S} \sum_{x \in U} \sum_{y \in Y} p_0(s, u, x, y) \ln \left( \frac{Q(u|y)}{Q(u|x)} \right)
\]

is the conditional probability mass function of \(U\) given \(Y\) under (A13). Let \(Q(u|y)\) be an arbitrary conditional probability mass function, and define

\[
F(q', q, Q) = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p_0(s, u, x, y) \ln \left( \frac{Q(u|y)}{Q(u|x)} \right)
\]

and

\[
U(q', q) = \sum_{s \in S} p(s) \max_{x \in X} \sum_{y \in Y} p(y|x, s) \ln \left( \frac{Q_0(u|y)}{Q_0(u|x)} \right)
\]

The derivation of the algorithm consists of four parts. First, we show \(C_{\text{conc}} = \max_{q'} \max_{q} \max_{Q} F(q', q, Q)\). Second, we show how to maximize \(F\) with respect to one argument when the other two arguments are fixed. Next, we show for fixed \(q'(x|u, s)\) and arbitrary \(q(u|y)\) that \(\max_{q} \max_{Q} F(q', q, Q) \leq U(q', q)\). Finally, we show that \(F_i\), the value of \(F\) after the \(i\)th iteration of the algorithm converges monotonically to \(F^* = C_{\text{conc}}\), and \(F^* = U^* = \text{the limit of } U_i\).

Part I:

From Theorem 2c) and the identity

\[
F(q', q, Q_0) = H(U|S) - H(U|Y) = I(U; Y) - I(U; S)
\]

we see that \(C_{\text{conc}} = \max_{q'} \max_{Q} F(q', q, Q_0)\). Thus, we need only show that \(F(q', q, Q_0) \geq F(q', q, Q)\):

\[
F(q', q, Q) - F(q', q, Q_0) = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p_0(s, u, x, y) \ln \left( \frac{Q(u|y)}{Q_0(u|y)} \right)
\]

\[
\leq \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p_0(s, i, x, y) \left[ \frac{Q(u|y)}{Q_0(u|y)} - 1 \right] = 0.
\]

The last step follows from the inequality \(\ln x \leq x - 1\).
Part 2:
The inequality $F(q', q, Q) \leq F(q', q, Q_0)$ from the previous section satisfies equality if and only if $Q(u|y) = Q_0(u|y)$ for all $u, y$ with $p_0(u, y) > 0$. Thus $F$ is maximized over $Q$ if and only if $Q$ is given by (A14).

To maximize $F$ over $q$ we form the functional

$$G(q) = F(q', q, Q) + \sum_{s \in S} \lambda_s \left( 1 - \sum_{u \in U} q(u|s) \right),$$

where the $\lambda$s are Lagrange multipliers. Since $G$ is concave in $q$, the maximum is found by setting the derivative of $G$ to zero.

Since

$$\frac{\partial G}{\partial q(u|s)} = p(s) \sum_{x \in X} \sum_{y \in Y} q'(x|u, s) p(y|x, s) \ln \left( \frac{Q(u|y)}{q(u|s)} \right) - 1 - \lambda_s$$

(A17)

$G$ is maximized for

$$q(u|s) = \frac{1}{1 + \sum_{u' \in U} \prod_{x \in X} \prod_{y \in Y} Q(u'|y) \sum_{u' \in U} \prod_{x \in X} \prod_{y \in Y} q(u'|x,y) \ln Q(u'|y)}.$$

Note $q \geq 0$ as required.

To maximize $F$ over $q'$ we rewrite $F$ as follows

$$F(q', q, Q) = H(U|S) + \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} p(s) q(u \leq s) q'(x|u, s) \cdot \sum_{y \in Y} p(y|x, s) \ln Q(u|y),$$

We see that $F$ is linear in $q'$. Thus $F$ is maximized for each $u$ and $s$ by setting $q^*(x|u, s) = 1$ for an $x$ which maximizes $\sum_{x \in X} p(y|x, s) \ln Q(u|y)$.

Thus $Q$ must maximize $F$ for fixed $q'$ and $q$. Second, $F$ is maximized over $q$ if and only if

$$\sum_{x \in X} q'(x|u, s) p(y|x, s) \ln \frac{Q(u|y)}{q(u|s)} Q_0(u|y) - 1 = 0, \quad \text{and}$$

where $Q_0(u|y)$ is the conditional probability mass function under $q(u|s)$. First, it is clear by the definitions that $U'(q', q, \tilde{q}) = U(q', q)$. We show that $F(q', q, Q) \leq U'(q', q, \tilde{q})$.

$$F(q', q, Q) - U'(q', q, \tilde{q}) = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} \sum_{y \in Y} p_0(s, u, x, y) \ln \frac{Q(u|y) Q_0(u|y)}{q(u|s)} - 1 = 0.$$

Part 3:
Fix $q'(x|u, s), q(u|s), \tilde{q}(u|s)$ and define

$$U'(q', q, \tilde{q}) = \sum_{s \in S} \sum_{u \in U} \sum_{x \in X} p(s) q(u \leq s) q'(x|u, s) \cdot \sum_{y \in Y} p(y|x, s) \ln \tilde{Q}_0(u|y) \tilde{q}(u|s),$$

where $\tilde{Q}_0(u|y)$ is the conditional probability mass function under $\tilde{q}(u|s)$. We derive necessary and sufficient conditions for $F(q', q, Q) = U(q', q)$.

$F(q', q, Q) = U(q', q, \tilde{q})$ if and only if for every $u$ and $y$ with $p_0(u, y) > 0$, we have $Q(u|y) = Q_0(u|y)$.

Part 4:
First, we show that we can maximize $F$ over $q$ and $Q$ for fixed $q'$. Define

$$p(y|u, s) = \sum_{x \in X} q'(x|u, s) p(y|x, s),$$

$$Q_0(u|y) = \frac{\sum_{s \in S} \sum_{u \in U} \sum_{x \in X} p(s) q(u \leq s) q'(x|u, s) \cdot \sum_{y \in Y} p(y|x, s) \ln Q(u|y)}{\sum_{s \in S} \sum_{u \in U} \sum_{x \in X} p(s) q(u \leq s) q'(x|u, s)},$$

$$r(u|s) = \sum_{y \in Y} Q_0(u|y) \ln Q_0(u|y).$$

and

$$F_{i+1} = F(q', q_{i+1}, Q_i).$$

We show that if $q_0(u|s) > 0$ then

$$\lim_{i \to \infty} F_i = C \triangleq \max_{q(u|s)} I(U; Y) - I(U; S).$$

and

$$p^*(s, u, y) = \frac{p(s) q^*(u|s) p(y|u, s)}{\sum_{u' \in U} \sum_{s \in S} \sum_{y \in Y} p(s) q^*(u|s) p(y|u, s)}$$

be probability mass functions on $S \times U \times Y$ and assume $q^*(u|s)$ achieves $C$. Consider

$$F_{i+1} = \sum_{s \in S} \sum_{u \in U} \sum_{y \in Y} p_{i+1}(s, u, y) \ln \frac{Q_0(u|y) Q_0(u|y)}{r_{i+1}(u|s)} + \sum_{s \in S} \sum_{u \in U} \sum_{y \in Y} p_{i+1}(s, u, y) \ln \frac{Q_0(u|y) Q_0(u|y)}{r_{i+1}(u|s)}.$$
Now,
\[
\sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{q_{i+1}(u|s)}{q_i(u|s)}
- \sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{r_{i+1}(u|s)}{q_i(u|s)} \sum_{u \in U} r_{i+1}(u|s)
= -F_{i+1} + \sum_{s \in S} \sum_{u \in U} p^*(s, u, y) \ln \frac{O(y|u)}{q_i(u|s)}
- F_{i+1} \sum_{s \in S} \sum_{u \in U} p^*(s, u, y) \ln \frac{P(y|u, s) p(s)}{p_i(y) p_i(s|u, y)}.
\]

The last step follows from the identity \( p_i(s, u, y) = p_i(s|u, y) p_i(u) p_i(y) \). We now see that
\[
\sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{q_{i+1}(u|s)}{q_i(u|s)}
= -F_{i+1} + \sum_{s \in S} \sum_{u \in U} p^*(s, u, y) \ln \frac{P(y|u, s) p(s)}{p_i(y) p_i(s|u, y)}
\leq -F_{i+1} + C,
\]
where the last inequality follows from the nonnegativity of the dropped term. Finally, we see
\[
\sum_{i=1}^{N-1} (C - F_{i+1}) \leq \sum_{i=1}^{N-1} \sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{q_{i+1}(u|s)}{q_i(u|s)}
\leq \sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{q_i(u|s)}{q_0(u|s)}
\leq \sum_{s \in S} \sum_{u \in U} p(s) q^*(u|s) \ln \frac{q_i(u|s)}{q_0(u|s)}.
\]

If \( q_0(u|s) > 0 \), the last term is finite and \( \sum_{i=1}^{N-1} C + F_{i+1} < \infty \). Since \( C \geq F_{i+1} \), we conclude that \( F_{i+1} \rightarrow C \) and this sequence converges. This shows that the algorithm for \( C_{\text{enc}} \) will maximize \( F \) over \( q \) and \( Q \). The upper bound \( U \) described in Part 3 will determine if \( C_{\text{enc}} - F < \epsilon \). If not, a new \( q' \) is chosen and the algorithm continues. Finally, since the set \( \mathcal{A}(q, Q) \) of admissible \( q' \)s is finite and the algorithm monotonically increases \( F \), it will eventually find a \( q' \) which achieves \( C_{\text{enc}} \). This establishes the convergence of the algorithm.

\begin{thebibliography}{99}
\end{thebibliography}
