# Katalin Marton's Lasting Legacy 

#### Abstract

This article highlights some of Katalin Marton's main contributions to rate distortion theory, probability theory, and multiuser information theory and their lasting impact on the work of many other researchers.

## Introduction

Katalin Marton (December 9, 1941-December 13, 2019) was a Hungarian mathematician who made important and lasting contributions to information theory and its applications in probability theory. In 2013, she became the first woman to win the Claude E. Shannon Award, the IEEE Information Theory Society's highest honor, established in 1972 to recognize profound and consistent contributions to the field. We describe some of her contributions and their lasting impact on the field and on the work of many researchers, including the authors.

The topics covered in this article represent a substantial part of Marton's work but are not comprehensive. We refer the readers to the obituary by Csiszár and Körner [16], her closest collaborators, for additional information about her work and her life.

Marton began her career during a revival in the late 1960s and early 1970s of Shannon's original 1948 and 1959 and Kolmogorov's 1956 work on rate distortion theory. She made several generalizations to Shannon's rate distortion and related results. A decade later and using similar tools, she was a co-founder of the field of distance-divergence inequalities, which played a fundamental role in the study of concentration of measure, bringing information theory tools to new audiences. Marton was a pioneer and a major contributor to multiuser information theory, especially the broadcast channel (BC). Her contributions to this problem ranged from defining new classes of BC to her namesake region, which remains as the tightest known inner bound on the capacity region of this channel. Another notable contribution of Marton to multiuser information theory is her result together with Körner on distributed computation of the modulo two sum of two sources. This result was the first

to show that structured codes can outperform random codes in multiuser communication and has had significant recent fol-low-on work.

## Rate Distortion Theory

Marton's earliest work, including her first publication [53], dealt with rate distortion theory, a branch of information theory first introduced by Shannon in his classic 1948 paper [83] in which he put forth the general model of a point-to-point communication system depicted in Figure 1. The source $X$ is a random object, which may be a random vector $X^{n}=$ $\left(X_{1}, X_{2}, \ldots, X_{n}\right)$, a discrete time random process $\left\{X_{n}: n \in\right.$ $\mathbb{Z}\}$, or a continuous time random process. To reliably communicate the source over the channel, an encoder maps the source outcome into a codeword $U$, which is then transmitted over the channel. To reproduce the source $X$, a decoder maps the corresponding channel output $V$ into an estimate $\hat{X}$. Shannon established necessary and sufficient conditions for reliable recovery of the source and showed for several classes of sources and channels the existence of ensembles of codes that can achieve these conditions.

When the channel is noiseless, i.e., $U=V$, with capacity $C$ bits/transmission, the communication model reduces to source coding or compression. Shannon showed that for a discrete time stationary process drawn from a discrete alphabet, the entropy rate $\bar{H}<C$ is necessary and sufficient for asymptotically lossless reproduction of the source. Motivated by a desire to extend this result to continuous alphabet sources, in Part V of [83] Shannon introduced the notion of fidelity in reproducing the source, which he quantified as the average "generalized distance" or "cost"-later called a distortion measure-between the source vector $x^{n} \in \mathcal{X}^{n}$ and its reproduction vector $\hat{x}^{n} \in \hat{\mathcal{X}}^{n}$. His primary example was a scalar or per-letter distortion measure $d\left(x_{1}, \hat{x}_{1}\right)$, which implied an additive distortion between the vectors of

$$
d_{n}\left(x^{n}, \hat{x}^{n}\right)=\sum_{i=1}^{n} d\left(x_{i}, \hat{x}_{i}\right)
$$

with the sum replaced by an integral for continuous time sources. Shannon defined a fidelity evaluation of a family of distributions $\left\{\mathrm{P}_{X^{n}, \hat{X}^{n}}: n=1,2, \ldots\right\}$ by the expected distortion $\mathrm{E}_{\mathrm{X}^{n}, \hat{X}^{n}}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) ; n=1,2, \ldots$ and the rate for $a$

Figure 1
source relative to a fidelity criterion, the rate distortion function of a stationary source, by

$$
\begin{align*}
R_{X}(D) & =\inf _{n} \frac{1}{n} R_{X^{n}}(D)=\lim _{n \rightarrow \infty} \frac{1}{n} R_{X^{n}}(D)  \tag{1}\\
R_{X^{n}}(D) & =\inf _{\mathrm{P}_{X^{n}, \hat{X}^{n} \in \mathcal{P}_{n}(D)} I\left(X^{n} ; \hat{X}^{n}\right)} \tag{2}
\end{align*}
$$

where, $I\left(X^{n} ; \hat{X}^{n}\right)$ is the mutual information between $X^{n}$ and $\hat{X}^{n}$, and $\mathcal{P}_{n}(D)$ is the collection of all joint distributions on ( $X^{n}, \hat{X}^{n}$ ) for which the marginal distribution on $X^{n}$ is $\mathrm{P}_{X^{n}}$, which can be abbreviated as $\mathrm{P}_{X^{n}, \hat{X}^{n}} \Rightarrow \mathrm{P}_{X^{n}}$, and

$$
\frac{1}{n} \mathrm{E}_{\mathrm{P}_{X^{n}, \hat{X}^{n}}}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) \leq D
$$

In [83, Th. 21], Shannon showed that when the source is iid, the abovementioned expression of $R_{X}(D)$ reduces to the sin-gle-letter ( $n=1$ ) and $R_{X}(D)<C$ is necessary and sufficient to reproduce the source with the specified distortion, and $R_{X}(D)$ naturally extends entropy to sources with continuous alphabets. Shannon established the achievability of $R_{X}(D)$ via random codebook generation using the the distribution resulting from the optimization defining $R_{X}(D)$ and limiting theorems relating sample distortion $d_{n} / n$ and information density $i_{n} / n$ to their expectations, where for discrete alphabets

$$
i_{n}\left(x^{n} ; y^{n}\right)=\log \frac{p_{X^{n}, Y^{n}}\left(x^{n}, y^{n}\right)}{p_{X^{n}}\left(x^{n}\right) p_{Y^{n}}\left(y^{n}\right)}
$$

and in general via the Radon-Nikodym derivative [39], [78]

$$
i_{n}\left(x^{n} ; y^{n}\right)=\log \frac{d \mathrm{P}_{X^{n}}, Y^{n}\left(x^{n}, y^{n}\right)}{d\left(\mathrm{P}_{X^{n}}\left(x^{n}\right) \times \mathrm{P}_{Y^{n}}\left(y^{n}\right)\right)}
$$

In both cases $\mathrm{E}_{\mathrm{P}_{X^{n}, Y^{n}}}\left(i_{n}\left(X^{n} ; Y^{n}\right)\right)=I\left(X^{n} ; Y^{n}\right)$.
When Marton entered the field, Shannon's rate distortion theorem had recently been generalized to stationary and ergodic sources with discrete and abstract alphabets in 1968 by Gallager [23] and in 1971 by Berger [4]. The heart of their general proofs remained the same as Shannon's, but the limiting results were more complicated. The convergence of information density to its expectation generated a new branch of information theory and ergodic theory-commonly called information stability or information ergodic theorems.

Marton likely learned of Shannon's rate distortion theory [83], [84] and contributions by Kolmogorov and his colleagues [39] during her 1969 visit to the Institute of

Problems of Information Transmission in Moscow, where Dobrushin and Pinsker both worked. Marton had met the two famous Russian information theorists in Hungary in 1967.

## Small D Asymptotics of $R_{X}(D)$

In her 1971 paper [53], Marton followed Kolmogorov's [39] "very significant interest ...in the investigations of the asymptotic behavior of the $\epsilon$ entropy as $\epsilon \rightarrow 0$ " and developed upper and lower bounds on the rate distortion function for finite alphabet stationary sources as $D$ approaches zero. Kolmogorov proposed renaming $R_{X}(D)$ as $\epsilon$-entropy $\bar{H}_{\epsilon}(X)$, where $\epsilon=D$, to better capture the notion of a generalization of entropy. Her general results are complicated, but in the case of Markov sources they take the simple form

$$
\bar{H}(X)-R_{X}(D)=\frac{1}{m_{r_{0}}} D \log \frac{1}{D}-O(D)
$$

where $m_{r_{0}}>0$ is a constant determined by the source and the fidelity criterion.

## Process Definitions of Rate Distortion Functions

Hidden in [53, Lemma 1] was an elaboration on a suggestion of Kolmogorov [39]-replacing the limits over finite dimensional optimizations of mutual information versus distortion in (1) and (2) by direct optimization over stationary processes In [56], Marton further developed this notion, demonstrating that for stationary sources with complete, separable metric space alphabets and an additive distortion measure, the rate distortion function is

$$
R_{X}(D)=\inf _{\mathrm{P}_{X, \hat{X}} \in \mathcal{P}} \bar{I}(X ; \hat{X})
$$

where $\mathcal{P}=\left\{\mathbf{P}_{X, \hat{X}}: \mathrm{P}_{X, \hat{X}} \Rightarrow \mathrm{P}_{X}, \mathrm{E}_{\mathrm{P}_{X, \hat{X}}}\left(d\left(X_{1}, \hat{X}_{1}\right)\right) \leq D\right\}$ and

$$
\bar{I}(X ; \hat{X})=\lim _{n \rightarrow \infty} \frac{1}{n} I\left(X^{n} ; \hat{X}^{n}\right)
$$

is the mutual information rate of the stationary process $(X, \hat{X})$. Marton also demonstrated that under some mild additional conditions on the distortion measure, the infimum is a minimum, so there is a stationary pair process that achieves the minimum. Reversing the order of limits and optimization in the definition of the rate distortion function has multiple benefits, primarily adding insight into the meaning of the rate distortion function from a process viewpoint
and simplifying previous proofs of Shannon's rate distortion theorem for general sources.

Finding such an optimal stationary pair process provides an alternative approach to the traditional extensions of Shannon's rate distortion theorem beyond iid processes. These traditional proofs require an information stability property for the mutual information densities that yield $R_{X^{n}}(D)$. In Shannon's original iid case, this property followed easily by the classic ergodic theorem. Subsequent generalizations were developed by proving such a property for more general sources. A major difficulty with the general stationary ergodic case was that an ergodic source need not produce ergodic sequences of $n$-dimensional vectors. Gallager [23] resolved this difficulty using a complicated source decomposition due to Nedoma. Berger [4] used the same technique to further generalize the result to abstract alphabet sources.

Marton's stationary process characterization of the rate distortion function provided an approach to creating a stationary pair process directly with the necessary properties to circumvent the Nedoma decomposition. Others eventually showed that one could also restrict the optimization to ergodic pair processes and that Shannon's approach could result in a generalization of the original iid theorem to stationary and ergodic sources with general alphabets. Marton's result was the catalyst to these simpler and more intuitive results; see, e.g., Gray and Saadat's work [34]. Process optimization also played a fundamental role in the development of Orstein's $\bar{d}$ distance [73], which was an important tool in his proof of the isomorphism theorem of ergodic theory establishing the role of equal Shannon entropy rate as necessary and, under additional assumptions, sufficient condition for isomorphism of two random processes. It is also a topic important to Marton's subsequent work.

## Information Stability of Stationary and Ergodic Processes

Marton's 1972 paper [54] extended to stationary ergodic processes a 1963 result of Pinsker [80] that stationary totally ergodic processes possessed the information stability property. This extension provided the key step in generalizing the proof of rate distortion theorem from totally ergodic sources to ergodic sources. Similar results were published in 1971 by Berger [4] in his generalization of his 1968 paper on the rate distortion theorem for totally ergodic sources. Both Marton and Berger followed Gallager [23] in their use of Nedoma's decomposition.

## Error Exponent for Rate Distortion for Discrete Iid Sources

In her 1974 paper [55], Marton derived the error exponent for rate distortion coding for discrete iid sources, a result analogous to the behavior of the error probability for
discrete memoryless channels (DMC) studied by Gallager, Shannon, and others. Given an iid source $X$, an additive distortion, $R>0, D>0, \delta>0$, and a reproduction codebook $\mathcal{C}_{n}$ of size $\left\|\mathcal{C}_{n}\right\|$, let

$$
d_{n}\left(x^{n}, \mathcal{C}_{n}\right)=\min _{\hat{x}^{n} \in \mathcal{C}_{n}} d_{n}\left(x^{n}, \hat{x}^{n}\right)
$$

and define the set of "bad" source sequences $B_{n}$ with respect to $\mathcal{C}_{n}$ by

$$
B_{n}=\left\{x^{n}: \frac{1}{n} d_{n}\left(x^{n}, \mathcal{C}_{n}\right)>D+\delta\right\}
$$

Finally, define

$$
\mathrm{P}^{n}(R, D)=\min _{\mathcal{C}_{n}:\left\|\mathcal{C}_{n}\right\| \leq 2^{n R}} \mathrm{P}_{X^{n}}\left(B_{n}\right)
$$

Gallager's proof of the source coding theorem shows that for $R>R_{X^{n}}(D), \lim _{n \rightarrow \infty} \mathrm{P}^{n}(R, D)=0$. Marton sharpened this result to show that for iid sources the convergence to zero is exponential for a range of $R>R_{X^{n}}(D)$, and that $\mathrm{P}^{n}(R, D)$ is otherwise bounded away from zero.

## Transportation and Measure Concentration

In 1986, Marton [57] introduced a simple inequality comparing a special case of the transportation cost and the informational divergence between two distributions. Optimal transport and the transportation cost date back over two centuries to Monge with its modern revival by Kantorovich. Its rich history and numerous applications in many fields are widely surveyed, see Villani's work [91], which provides more than 800 references as well as a chapter on concentration of measure that describes Marton's contributions to both topics of this section's title.

Transportation cost has appeared under many names, including Monge (1878), Kantorovich (1942), Ornstein's $\bar{d}$ (d-bar) (1970), Mallows (1972), and Vasershtein/Wasserstein (1969). Informational divergence, also known as relative entropy and Kullback-Leibler divergence, was introduced in 1951 by Kullback and Leibler [46] as a generalization of Shannon's entropy and developed as arguably the most fundamental of the Shannon-style information measures; see, e.g., Pinsker [78] and Kullback's work [47]. Both notions began with finitedimensional distributions and were later extended to process distributions.

According to Ledoux [49], the investigation of distancedivergence inequalities, also known as transportation costinformation and transport-entropy inequalities, began in the 1990s with works by Marton [58], [59], and Talagrand [87] in connection with the concentration of measure phenomenon for product measures. The key result by Marton in her

1996 papers in its original finite-dimensional form for discrete sources and Hamming distance appeared a decade earlier [57] in her simple information theoretic proof of the blowing-up lemma, which is discussed later.

## Transportation and Marton's Inequality

Marton's setup in [57, Lemma 1] strongly resembles Shannon's. Given a joint distribution $\mathrm{P}_{X^{n} . \hat{X}^{n}}$ describing a pair of random vectors ( $X^{n}, \hat{X}^{n}$ ), Shannon optimized mutual information for two cases: fixing a conditional distribution and maximizing over all source distributions $\mathrm{P}_{X^{n}}$ (channel capacity) or fixing the source distribution and minimizing over all conditional distributions satisfying a fidelity criterion $\mathrm{E}_{\mathrm{X}_{X^{n}, \hat{X}^{n}}}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) \leq n D$ (rate distortion). In transportation theory or optimal transportation, the marginal distributions $P_{X^{n}}$ and $P_{\hat{X}^{n}}$ are fixed and the average distortion between them is minimized over the collection $\mathcal{P}_{n}$ of all joint distributions $\mathrm{P}_{X^{n}, \hat{X}^{n}}$ (or couplings) consistent with the given marginals. This defines a transportation cost between finitedimensional distributions

$$
\begin{equation*}
\mathcal{T}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right)=\inf _{\mathrm{P}_{X^{n}, \hat{X}^{n} \in \mathcal{P}_{n}}} \mathrm{E}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) . \tag{3}
\end{equation*}
$$

Sometimes with limits in mind, a normalization $1 / n$ is included on the right-hand side. The resemblance between the transportation problem and Shannon information optimizations has been exploited in the rate distortion literature, e.g., Gray et al.'s work [33].

The name optimal transportation was coined by Kantorovich in 1948 when he realized his cost function introduced in 1942 [37] was equivalent to a 1781 problem of Monge regarding the best way of transporting a pile of dirt of one shape into another. Two special cases are important here: 1) the case of Hamming distance, where (3) becomes Ornstein's $\bar{d}_{n}$ distance [73], [74]

$$
\begin{align*}
\mathcal{T}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) & =\bar{d}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) \\
& =\inf _{\mathrm{P}_{X^{n}, \hat{X}^{n}} \in \mathcal{P}_{n}} \frac{1}{n} \sum_{i=1}^{n} \mathrm{P}\left\{X_{i} \neq \hat{X}_{i}\right\} \tag{4}
\end{align*}
$$

and 2) the case of squared-error distortion, where (3) becomes

$$
\begin{align*}
\mathcal{T}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) & =W_{2}^{2}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) \\
& =\inf _{\mathrm{P}_{X^{n}, \hat{x}^{n}} \in \mathcal{P}_{n}} \mathrm{E}_{\mathrm{P}_{X^{n}, \hat{X}^{n}}}\left\|X^{n}-\hat{X}^{n}\right\|_{2}^{2} . \tag{5}
\end{align*}
$$

The square root $W_{2}$ of this cost is a metric, commonly known as the Wasserstein distance. It is worth noting here that Wasserstein is the German spelling of the Russian mathematician Leonid Vasershtein, who developed properties of the distance in 1969, which were popularized by Dobrushin [18].

In Lemma 1 of [57], Marton proved the following inequality for random variables with complete separable metric space alphabet and Hamming distance.

Lemma 1. Let $X^{n} \sim \prod_{i=1}^{n} \mathrm{P}_{X_{i}}$ and $\hat{X}^{n} \sim \mathrm{P}_{\hat{X}^{n}}$. Then, there exists a joint probability measure $\mathrm{P}_{X^{n}, \hat{X}^{n}}$ with these given marginals such that

$$
\begin{aligned}
\frac{1}{n} \mathrm{E}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) & =\frac{1}{n} \sum_{i=1}^{n} \mathrm{P}\left\{X_{i} \neq \hat{X}_{i}\right\} \\
& \leq\left(\frac{1}{n} D\left(\mathrm{P}_{\hat{X}^{n}} \| \prod_{i=1}^{n} \mathrm{P}_{X_{i}}\right)\right)^{1 / 2}
\end{aligned}
$$

where, $D(\mathrm{P} \| \mathrm{Q})=\mathrm{E}_{\mathrm{P}}(\log (\mathrm{P} / \mathrm{Q}))$ is the relative entropy between the distributions $P$ and $Q$.

Hence from (4)

$$
\begin{equation*}
\bar{d}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) \leq\left(\frac{1}{n} D\left(\mathrm{P}_{\hat{X}^{n}} \| \prod_{i=1}^{n} \mathrm{P}_{X_{i}}\right)\right)^{1 / 2} . \tag{6}
\end{equation*}
$$

Marton later showed [58], [60] that better constants were possible, but that in general if for some $\rho>0$ and for all $\mathrm{P}_{\hat{X}^{n}}$, a distribution $\mathrm{P}_{X^{n}}$ on $n$-dimensional Euclidean space satisfies the "distance-divergence inequality"

$$
\begin{equation*}
\mathcal{T}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) \leq\left(\frac{2}{\rho} D\left(\mathrm{P}_{\hat{X}^{n}} \| \mathrm{P}_{X^{n}}\right)\right)^{1 / 2} \tag{7}
\end{equation*}
$$

then, $\mathrm{P}_{X^{n}}$ has the measure concentration property.
Ornstein [73] developed the process version of the $\bar{d}$ distance as a key tool for proving his isomorphism theorem of ergodic theory: For stationary processes $X$ and $\hat{X}$

$$
\bar{d}\left(\mathrm{P}_{X}, \mathrm{P}_{\hat{X}}\right)=\sup _{n} \bar{d}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right)=\lim _{n \rightarrow \infty} \bar{d}_{n}\left(\mathrm{P}_{X^{n}}, \mathrm{P}_{\hat{X}^{n}}\right) .
$$

A key property of $\bar{d}$ is that it could also be defined directly as the single-letter optimization problem

$$
\begin{equation*}
\bar{d}\left(\mathrm{P}_{X}, \mathrm{P}_{\hat{X}}\right)=\bar{d}_{1}\left(\mathrm{P}_{X_{1}}, \mathrm{P}_{\hat{X}_{1}}\right) . \tag{8}
\end{equation*}
$$

Marton [58] used the information stability of informational divergence to relate the $\bar{d}$ distance to the relative entropy rate between an arbitrary stationary process $\hat{X}$ and an iid process $X$

$$
\bar{D}\left(\mathrm{P}_{\hat{X}} \| \mathrm{P}_{X}\right) \lim _{n \rightarrow \infty} \frac{1}{n} D\left(\mathrm{P}_{\hat{X}^{n}} \| \mathrm{P}_{X^{n}}\right)
$$

to obtain

$$
\begin{equation*}
\bar{d}\left(\mathrm{P}_{X}, \mathrm{P}_{\hat{X}}\right) \leq\left(\bar{D}\left(\mathrm{P}_{\hat{X}} \| \mathrm{P}_{X}\right)\right)^{1 / 2} . \tag{9}
\end{equation*}
$$

This is the process version of her inequality and was the first inequality to relate limiting transportation cost and relative entropy rate.

Follow-on work: Talagrand [88] extended Marton's inequality in the finite-dimensional case from Hamming distortion to squared-error distortion and Gaussian product measures. This led to his follow-on work on measure concentration from Marton's for Hamming distortion to Gaussian iid processes and squared error.

Asymptotically optimal source codes resemble fair coin flips: The process version of Marton's inequality (9) easily yields a rigorous proof of a variation on a common intuition of rate distortion theory-if a source coding system has nearly optimal performance, then the bits produced by the encoder should resemble fair coin flips; see, e.g., Problem 10.9 for iid sources in Cover and Thomas's work [15]. Gray and Linder [32] established a rigorous result in this direction, with Marton's inequality providing the key step.

Shannon and the bulk of the literature consider block codes. Block codes applied to a stationary ergodic source, however, do not in general produce either a stationary or ergodic channel sequences or reproduction sequence or a combination of the three processes. This complicates drawing conclusions about the properties of the channel process. In his proof of the isomorphism theorem of ergodic theory [74], Ornstein developed techniques for converting block codes into stationary codes (sliding-block or sliding window codes), which inherit useful statistical properties of the block codes they are built upon, such as average distortion and information, and also produce jointly stationary source/encoded source processes, which are also ergodic if the source is. Shannon's rate distortion theorem holds for such stationary codes; see, e.g., [31] and the references therein. Pursuing a 1 -bit per source sample noiseless channel example, consider the dual Shannon source coding problem of distortion rate theory. The inverse of Shannon's rate distortion function from Marton's process definition [56] is

$$
D_{X}(R)=\inf _{\mathrm{P}_{X, \hat{X}}: \mathrm{P}_{X, \hat{X}} \Rightarrow \mathrm{P}_{X}, \bar{I}(X ; \hat{X}) \leq R} \mathrm{E}\left(d\left(X_{1}, \hat{X}_{1}\right)\right)
$$

The stationary codes version of Shannon's source coding theorem implies there exists a sequence of stationary encoder/ decoder pairs $f^{(m)}, g^{(m)}$ resulting in a channel process $U^{(m)}$ and reproduction process $\hat{X}^{(m)}$ for which

$$
\lim _{m \rightarrow \infty} \mathbb{E}_{\mathrm{P}_{X}}\left(d\left(X_{1}, \hat{X}_{1}^{m)}\right)\right)=D_{X}(1)
$$

If a sequence of encoder-decoder pairs satisfies the Shannon limit, it is said to be asymptotically optimal. The original version of Marton's inequality (9) combined with standard information theoretic inequalities easily yields the following.

Theorem [32], [51]. Let $X$ be a stationary ergodic source with Shannon distortion-rate function $D_{X}(R)$. Let $Z$ denote the process of independent fair coin flips, that is, a Bernoulli process with parameter $1 / 2$. If sliding-block source codes $f^{(m)}, g^{(m)}$ are asymptotically optimal, then $\lim _{m \rightarrow \infty} \bar{d}\left(\mathrm{P}_{U^{(m)}}, \mathrm{P}_{Z}\right)=0$, that is, the encoder output bits converge to iid coin flips in $\bar{d}$.

Bounds on the capacity of multiuser channels: Marton and Talagrand's distance-divergence inequalities have played a crucial role in the work of Polyanskiy and Wu [81] on the interference channel. They used Talagrand's inequality to resolve the missing corner point problem of Costa for the Gaussian interference channel; see Costa [11] and Sason's work [82], and to obtain an outer bound on its capacity region, and Marton's inequality (6) to establish an outer bound for the discrete memoryless case. Both inequalities provided a critical step in quantifying an approximation error in the output entropy when an input distribution induced by a codebook is replaced by its iid approximation. More recently, Bai et al. [3] incorporated an information constraint into the optimization defining the transportation cost for the squared-error distortion and generalized Talagrand's distance-divergence inequality for squared error to this constrained case. This led to further follow-on work to Marton's applications of her inequality, including blowing-up, measure concentration, and Cover's relay channel problem.

## Blowing-Up Lemma

Marton's initial version of her distance-divergence inequality was developed as part of her simple proof for the blowing-up lemma, which was first introduced by Margulis [52] in the study of probabilistic properties of large random graphs. His result was later improved by Ahlswede et al. [1] who used it to establish a strong converse for the degraded BC by enhancing the known weak converse. Later, Zhang [100] and Xue [98] used it to show that the capacity of the relay channel can be strictly smaller than the cutset bound in Cover and El Gamal work [14]. Using simpler and more refined arguments together with the blowing-up lemma, Wu et al. [97] obtained tighter bounds than in Xue [98] and Zhang's work [100].

Marton [57] provided a significantly simpler information theoretic proof of the blowing-up lemma, which we outline here as a demonstration of her knack for simple and elegant proofs. Let $\mathcal{X}$ be a finite alphabet, $x^{n}, y^{n} \in \mathcal{X}^{n}$, and $d_{n}\left(x^{n}, y^{n}\right)$ be the Hamming distance between $x^{n}$ and $y^{n}$. Let $\mathcal{A} \subseteq \mathcal{X}^{n}$ and for $l \leq n$, let $\Gamma_{l}(\mathcal{A})=\left\{x^{n}: \min _{y^{n} \in \mathcal{A}} d_{n}\left(x^{n}, y^{n}\right) \leq l\right\}$, as shown in Figure 2. Blowing-up Lemma: Let $X^{n} \sim \mathrm{P}_{X^{n}}=\prod_{i=1}^{n} \mathrm{P}_{X_{i}}$ and $\epsilon_{n} \rightarrow 0$ as $n \rightarrow \infty$. There exist $\delta_{n}, \eta_{n} \rightarrow 0$ as $n \rightarrow \infty$ such that if $\mathrm{P}_{X^{n}}(\mathcal{A}) \geq 2^{-n \epsilon_{n}}$, then $\mathrm{P}_{X^{n}}\left(\Gamma_{n \delta_{n}}(\mathcal{A})\right) \geq 1-\eta_{n}$.

To prove this lemma, define

$$
\mathrm{P}_{\hat{X}^{n}}\left(x^{n}\right)=\mathrm{P}_{X^{n} \mid \mathcal{A}}\left(x^{n}\right)=\left\{\begin{array}{cl}
\mathrm{P}_{X^{n}}\left(x^{n}\right) \mathrm{P}_{X^{n}}(\mathcal{A}) & \text { if } x^{n} \in \mathcal{A} \\
0 & \text { if } x^{n} \notin \mathcal{A}
\end{array}\right.
$$

Figure 2
Two sets in the blowing-up lemma.
Then

$$
D\left(\mathrm{P}_{\hat{X}^{n}} \| \prod_{i=1}^{n} \mathrm{P}_{X_{i}}\right)=-\log \mathrm{P}_{X^{n}}(\mathcal{A}) \leq n \epsilon_{n}
$$

By Lemma 1, there exists $\mathrm{P}_{X^{n}, \hat{X}^{n}}$ with the given marginals such that

$$
\mathrm{E}\left(d_{n}\left(X^{n}, \hat{X}^{n}\right)\right) \leq n \sqrt{\epsilon_{n}}
$$

By the Markov inequality, it follows that:

$$
\mathrm{P}_{X^{n}, \hat{X}^{n}}\left\{d_{n}\left(X^{n}, \hat{X}^{n}\right) \leq n \delta_{n}\right\} \geq 1-\frac{\sqrt{\epsilon_{n}}}{\delta_{n}}=1-\eta_{n}
$$

where, we choose $\delta_{n} \rightarrow 0$ such that $\eta_{n} \rightarrow 0$ as $n \rightarrow \infty$. We therefore have

$$
\begin{aligned}
\mathrm{P}_{X^{n}}\left(\Gamma_{n \delta_{n}}(\mathcal{A})\right)= & \mathrm{P}_{X^{n}, \hat{X}^{n}}\left(\Gamma_{n \delta_{n}}(\mathcal{A}) \times \mathcal{A}\right) \\
& +\mathrm{P}_{X^{n}, \hat{X}^{n}}\left(\Gamma_{n \delta_{n}}(\mathcal{A}) \times \mathcal{A}^{c}\right) \\
\stackrel{(a)}{=} & \mathrm{P}_{X^{n}, \hat{X}^{n}}\left(\Gamma_{n \delta_{n}}(\mathcal{A}) \times \mathcal{A}\right) \\
\geq & \mathrm{P}_{X^{n}, \hat{X}^{n}}\left\{d_{n}\left(X^{n}, \hat{X}^{n}\right) \leq n \delta_{n}\right\} \geq 1-\eta_{n}
\end{aligned}
$$

where, (a) follows since $P_{X^{n}, \hat{X}^{n}}\left(x^{n}, \hat{x}^{n}\right)=0$ if $\hat{x}^{n} \notin \mathcal{A}$.
Follow-on work: In a series of papers Paul Shields with Marton developed applications of the blowing up and related properties to a variety of stationary random processes studied by Ornstein and his colleagues, including weak and very weak Bernoulli processes, and $B$ processes. See, e.g., Shields's work [85] and the references therein.

## Concentration of Measure

Although Marton's initial version of her distance-divergence inequality was developed as part of her simple proof of the blowing-up lemma, which had its original applications in random graph theory and strong converse proofs in multiuser information theory, its major impact came later as a new and powerful tool in the field of concentration of measure. It worth noting, however, that while not originally developed with measure concentration in mind, the blowing-up lemma can be viewed as a concentration inequality.

The theory of concentration of measure arose in the 1970s as a branch of analysis and probability emphasizing the study of asymptotic properties of certain measures and probability
distributions, specifically conditions under which a set of positive probability can be expanded very slightly to asymptotically contain most of the probability. At its heart are inequalities that bound, as $n$ grows, the probability of a function of $n$ samples differing from its expectation by more than $\epsilon$ as $n$ grows. In Marton's words, "measure concentration is an important property, since it implies sub-Gaussian behavior of the Laplace transforms of Lipschitz functions and thereby is an important tool for proving strong forms of the law of large numbers" [60].

In 1996, Marton [58] used her inequality relating the $\bar{d}$ distance on processes and the relative entropy rate to develop a new approach to proving and extending concentration inequalities, beginning with product distributions (e.g., iid processes) and later extending her results to a class of Markov processes [58], [59], [60].

Follow-on work: Concentration inequalities have proven to be important in analysis, probability, and related areas, such as information theory and signal processing. A good survey including history and the contributions of Marton can be found in Ledoux's work [49]. As stated earlier, Talagrand [88] extended Marton's inequality to squared error and used her method to extend the measure conservation property to iid Gaussian processes; see also Marton's work [60]. In 1997, Dembo [17] used Marton's approach to develop new proofs and sharper versions of many of Talagrand's results on transportation information inequalities. See also Ledoux [49] and Villani [91], who lists several subsequent works following Marton's approach. In his bibliographic notes to Chapter 22, Villani [91] stated that "It is also Marton who introduced the simple argument by which [transportation] inequalities lead to concentration inequalities...which has since then been reproduced in nearly all introductions to the subject." Boucheron et al. [7] also included both a history of concentration inequalities and Marton's role in it along with many applications of her methods by them and others.

## Broadcast Channel

In a pioneering paper in multiuser information theory, which aims to extend Shannon's point-to-point information theory to communication networks, Cover [12] introduced the BC model depicted in Figure 3. The sender $X$ wishes to reliably communicate a private message $M_{i} \in\left[1: 2^{n R_{i}}\right]$ to receiver $Y_{i}, i=1,2$, and a common message $M_{0} \in\left[1: 2^{n R_{0}}\right]$ to both receivers. A rate triple $\left(R_{0}, R_{1}, R_{2}\right)$ is said to be achievable if there exists a sequence of codes with this rate triple such that the probability of decoding error can be made as small as desired. The capacity region of this channel is the closure of the set of achievable rate triples; see, e.g., El Gamal and Kim's work [21] for more details. The capacity region of the BC is not known in general and is considered one of the most important open problems in the field. Marton jointly with
$\left(M_{0}, M_{1}, M_{2}\right) \longrightarrow$ Encoder $\xrightarrow{X^{n}}{ }^{\square} p\left(y_{1}, y_{2} \mid x\right) \xrightarrow{Y_{1}^{n}}$ Decoder 1 $\longrightarrow\left(\hat{M}_{01}, \hat{M}_{1}\right)$
Figure 3

Körner and Csiszár made some of the key early contributions toward solving this problem.

## Less Noisy and More Capable

Cover [12] introduced the technique of superposition coding and illustrated it via the binary symmetric BC and Gaussian BC with average transmission power constraint. He then noted that these two example BCs are instances of the class of degraded BC.

Degraded BC: Given a BC $p\left(y_{1}, y_{2} \mid x\right), Y_{2}$ is said to be a degraded version of $Y_{1}$ if there exists a channel $p\left(y_{1}^{\prime} \mid x\right)=$ $p\left(y_{1} \mid x\right)$ such that $X \rightarrow Y_{1}^{\prime} \rightarrow Y_{2}$ form a Markov chain.

Cover conjectured that the capacity region of the degraded BC coincides with the superposition coding region, which we express in the form in Wang et al.'s work [94] that naturally extends to the more general inner bounds discussed later.

Superposition coding inner bound: A rate triple $\left(R_{0}, R_{1}, R_{2}\right)$ is achievable for the BC $p\left(y_{1}, y_{2} \mid x\right)$ if it satisfies the conditions

$$
\begin{align*}
R_{2}+R_{0} & <I\left(U ; Y_{2}\right) \\
R_{1} & <I\left(V ; Y_{1} \mid U\right) \\
R_{1}+R_{2}+R_{0} & <I\left(U, V ; Y_{1}\right) \tag{10}
\end{align*}
$$

for some probability mass function (pmf) $p(u) p(v)$ and function $x(u, v)$, where $U$ and $V$ are auxiliary random variables, that is, random variables that are not defined by the channel itself.

It is not difficult to see that $I\left(V ; Y_{1} \mid U\right)=I\left(X ; Y_{1} \mid U\right)$ and $I\left(U, V ; Y_{1}\right)=I(X ; Y)$, which yields an equivalent description of the region in (10) for which achievability was settled by Bergmans [5] and the converse was established by Gallager [24] via an ingenious identification of the auxiliary random variable $U$. Gallager also established a bound on the cardinality of $U$, which renders the region "computable."

The achievability of the superposition region uses random codebook generation. Fix $p(u) p(v)$ and a function $x(u, v)$. We use $p(u)$ and $p(v)$ to randomly and independently generate codebooks $\left\{u^{n}\left(m_{0}, m_{2}\right):\left(m_{0}, m_{2}\right) \in\left[1: 2^{n R_{0}}\right] \times\left[1: 2^{n R_{2}}\right]\right\}$ and $\left\{v^{n}\left(m_{1}\right) m_{1} \in\left[1: 2^{n\left(R_{1}\right)}\right]\right\}$, respectively. To send $\left(m_{0}, m_{1}, m_{2}\right)$, the encoder sends $x\left(u_{i}\left(m_{0}, m_{2}\right), v_{i}\left(m_{1}\right)\right)$ in transmission $i \in[1: n]$. Receiver $Y_{1}$ uses joint typicality
decoding to recover ( $m_{0}, m_{1}, m_{2}$ ) and receiver $Y_{2}$ similarly recovers $\left(m_{0}, m_{2}\right)$. It can be shown that the decoding error can be made as small as desired if the conditions in (10) are satisfied. One of Marton and Körner's early contributions to the BC problem [40] was to extend the notion of degradedness to define the following more general classes of BCs for which any message that can be recovered by $Y_{2}$ can be (essentially) recovered by $Y_{1}$.

Less noisy $B C$ : Given a $\mathrm{BC} p\left(y_{1}, y_{2} \mid x\right), Y_{1}$ is said to be less noisy than receiver $Y_{2}$ if $I\left(U ; Y_{1}\right) \geq I\left(U ; Y_{2}\right)$ for every $p(u, x)$.

More capable BC: Given a $\mathrm{BC} p\left(y_{1}, y_{2} \mid x\right), Y_{1}$ is said to be more capable than $Y_{2}$ if $I\left(X ; Y_{1}\right) \geq I\left(X ; Y_{2}\right)$ for every $p(x)$.

It is not difficult to see that the degraded condition implies less noisy, which in turn implies more capable. Körner and Marton showed through examples that these relations are strict. They also showed that superposition coding is optimal for the less noisy BC.

Follow-on work: One of El Gamal's earliest results was to show that superposition coding is optimal for the more capable BC [19]. Van Dijk [90] introduced the following alternate form of the less noisy condition which proved to be easier to compute and has helped lead to several of the follow-on results discussed later.

Less noisy via concave envelope: $Y_{1}$ is less noisy than $Y_{2}$ if $\left(I\left(X ; Y_{1}\right)-I\left(X ; Y_{2}\right)\right)$ is concave in $p(x)$.

Essentially and effectively less noisy: The definitions of less noisy and more capable BC classes require the mutual information conditions in each case to hold for all distributions. By judiciously restricting the set of distributions over which these conditions apply, extensions of less noisy and more capable for which superposition coding continues to be optimal were introduced.

Motivated by a BC example in which the channel from $X$ to $Y_{1}$ is a binary symmetric channel with parameter $p$ and the channel from $X$ to $Y_{2}$ is a binary erasure channel with parameter $\epsilon$, Nair [67] introduced the notion of essentially less noisy BC . As the parameters of this BC example are varied, it is not difficult to show that: 1) for $0<\epsilon \leq 2 p, Y_{1}$ is a degraded version of $Y_{2}, 2$ ) for $2 p<\epsilon \leq 4 p(1-p), Y_{2}$ is less
noisy than $Y_{1}$ but $Y_{1}$ is not a degraded version of $Y_{2}$, and 3) for $4 p(1-p)<\epsilon \leq H(p), Y_{2}$ is more capable than $Y_{1}$ but not less noisy. For the remaining range, $H(p)<\epsilon<1$, Nair showed that $Y_{2}$ is essentially less noisy than $Y_{1}$. Nair also showed that less noisy implies essentially less noisy, but that the reverse does not always hold. He also showed that essentially less noisy does not necessarily imply more capable.

Kim et al. [38] introduced the notion of effectively less noisy and showed that it implies essentially less noisy while being more straightforward to verify computationally. They used this notion along with degraded, less noisy, and more capable to show that superposition coding is almost always optimal for the Poisson BC.

More than two receivers: The notions of degraded, less noisy, and more capable can be readily extended to BCs with more than two receivers. It is straightforward to show that superposition coding is optimal for degraded BC with an arbitrary number of receivers. Nair and Wang [64] showed that superposition coding is also optimal for three-receiver less noisy BCs. However, Nair and Xia [65] showed via an example that superposition coding is not necessarily optimal for threereceiver more capable BCs.

## Degraded Message Sets

Consider the BC in Figure 3 with $M_{2}=\emptyset$ or equivalently $R_{2}=0$. In this setting referred to as BC with degraded message sets, the sender wishes to communicate a private message $M_{1}$ to receiver $Y_{1}$ and a common message $M_{0}$ to both receivers. Körner and Marton [41] showed that the capacity region for this setting coincides with the superposition coding region in (10) with $R_{2}=0$. They established a strong converse using the technique of images of a set [42], which is in itself an important contribution by Marton.

Images of a set: Let $p(y \mid x)$ be a DMC and let $p(x)$ be a pmf over its input alphabet $\mathcal{X}$. For $0<\epsilon<1$, let $A_{n}, n=$ $1,2, \ldots$, be a subset of the set of $\epsilon$-typical sequences $\mathcal{T}_{\epsilon}^{(n)}(p(x))$. The set $B_{n} \subset \mathcal{Y}^{n}$ such that $\mathrm{P}\left(B_{n} \mid x^{n}\right) \geq 1-\epsilon$ for every $x^{n} \in A_{n}$ is called the $(1-\epsilon)$-image of $A_{n}$ under the channel $p(y \mid x)$. Let $g_{n}\left(A_{n}, 1-\epsilon\right)$ be the cardinality of the smallest such set. Körner and Marton [42] showed that $g_{n}$ plays an important role in constructing codes for the DMC.

Maximal code lemma: For sufficiently large $n$, there exists a codebook for the DMC $p(y \mid x)$, which is a subset of $A_{n}$, with maximal probability of decoding error no greater than $\epsilon$ and rate

$$
R \geq \frac{1}{n} \log g_{n}\left(A_{n}, 1-\epsilon\right)-H(Y \mid X)-\epsilon
$$

While results of this nature had origins in works as early as 1954 by Feinstein, the main contribution of Körner and Marton was to develop a similar theory for images of a set over
two channels with the same input, which involved extensions of the maximal code lemma and new ideas for identification of auxiliary random variables in converse proofs. This enabled them to establish the capacity region of the BC with degraded message sets and played a central role in their definitions of the classes of less noisy and more capable BCs discussed earlier.

Follow-on work: The notion of degraded message sets can be extended in many ways to more than two receivers. Borade et al. [6] considered a multilevel $B C$ which for the threereceiver case is defined by $p\left(y_{1}, y_{3} \mid x\right) p\left(y_{2} \mid y_{1}\right)$, i.e., $Y_{2}$ is a degraded version of $Y_{1}$, where $M_{0}$ is to be communicated to all receivers and $M_{1}$ is to be communicated only to receiver $Y_{1}$. Nair and El Gamal [68] showed that superposition coding is not in general optimal for this BC and established the capacity region using the technique of indirect coding.

Nair and Wang [69] considered the three-receiver BC in which $M_{0}$ is to be reliably communicated to all receivers and $M_{1}$ is to be communicated only to receivers $Y_{1}$ and $Y_{2}$ and showed that superposition is optimal for several special cases. Nair and Yazdanpanah [66] then showed that superposition coding is not in general optimal for this setting.

## Marton Region

Marton is most famous in multiuser information theory for establishing the tightest known inner bound on the capacity region of the BC in Marton's work [61]. We describe the journey that culminated into the establishment of her inner bound.

In 1975, Cover [13] and van der Meulen [89] independently established the following inner bound on the capacity region of the BC.

Cover-van der Meulen region: A rate triple $\left(R_{0}, R_{1}, R_{2}\right)$ is achievable for the BC $p\left(y_{1}, y_{2} \mid x\right)$ if it satisfies the following conditions:

$$
\begin{align*}
R_{0}+R_{1} & <I\left(W, V ; Y_{1}\right) \\
R_{0}+R_{2} & <I\left(W, U ; Y_{2}\right) \\
R_{0}+R_{1}+R_{2} & <I\left(W, V ; Y_{1}\right)+I\left(U ; Y_{2} \mid W\right) \\
R_{0}+R_{1}+R_{2} & <I\left(V ; Y_{1} \mid W\right)+I\left(W, U ; Y_{2}\right) \tag{11}
\end{align*}
$$

for some $\operatorname{pmf} p(w) p(u \mid w) p(v \mid w)$ and function $x(w, u, v)$.
It is straightforward to see that by setting $W=U$ and $V=\emptyset$ and with some simple manipulations, we obtain the superposition coding region in (10).

The achievability of the Cover-van der Meulen inner bound involves a new idea beyond the proof for the superposition coding inner bound, which is rate splitting. We split $M_{j}, j=1,2$, into two independent parts, a common part
$M_{j 0} \in\left[1: 2^{n R_{j 0}}\right]$ and a private part $M_{j j} \in\left[1: 2^{n R_{j j}}\right]$, hence $R_{j}=R_{j 0}+R_{j j}$. Fix $p(w) p(u \mid w) p(v \mid w)$ and a function $x(w, u, v)$ according to $p(w)$. Randomly and independently generate a codebook $\left\{w^{n}\left(m_{0}, m_{01}, m_{02}\right)\right\}$, and conditioned on $w^{n}\left(m_{0}, m_{01}, m_{02}\right)$, randomly and conditionally independently generate codebooks $\left\{u^{n}\left(m_{0}, m_{01}, m_{02}, m_{22}\right)\right\},\left\{v^{n}\left(m_{0}, m_{01}\right.\right.$, $\left.\left.m_{02}, m_{11}\right)\right\}$ according to $p(u \mid w)$ and $p(v \mid w)$, respectively. To send ( $m_{0}, m_{1}, m_{2}$ ), the encoder sends $x\left(w_{i}\left(m_{0}, m_{01}, m_{02}\right)\right.$, $\left.u_{i}\left(m_{0}, m_{o 1}, m_{02}, m_{11}\right), v_{i}\left(m_{0}, m_{o 1}, m_{02}, m_{11}\right)\right)$ at transmission $i \in[1: n]$. Receiver $Y_{1}$ recovers $\left(m_{0}, m_{01}, m_{02}, m_{11}\right)$ and receiver $Y_{2}$ recovers ( $m_{0}, m_{01}, m_{02}, m_{22}$ ). Using standard arguments and Fourier-Motzkin elimination completes the proof; see El Gamal and Kim's work [21].

The search for a tighter inner bound began with a paper in 1977 by Gelfand [25] in which he established the capacity region of the Blackwell deterministic BC with input $X \in$ $\{0,1,2\}$ and outputs $Y_{1}, Y_{2} \in\{0,1\}$, where for $X=0, Y_{1}=$ $Y_{2}=0$, for $X=1, Y_{1}=Y_{2}=1$, and $X=2, Y_{1}=0, Y_{2}=1$. In 1978, Pinsker [79] generalized Gelfand's result to establish the capacity region of the deterministic BC. This result was further generalized to the semideterministic BC independently by Marton [61] and Gelfand and Pinsker [26]. These efforts culminated in the following inner bound on the capacity region of the general BC [61].

Marton region: A rate triple $\left(R_{0}, R_{1}, R_{2}\right)$ is achievable for the BC $p\left(y_{1}, y_{2} \mid x\right)$ if it satisfies the following conditions:

$$
\begin{align*}
R_{0}+R_{1} & <I\left(W, V ; Y_{1}\right) \\
R_{0}+R_{2} & <I\left(W, U ; Y_{2}\right) \\
R_{0}+R_{1}+R_{2} & <I\left(W, V ; Y_{1}\right)+I\left(U ; Y_{2} \mid W\right)-I(U ; V \mid W) \\
R_{0}+R_{1}+R_{2} & <I\left(V ; Y_{1} \mid W\right)+I\left(W, U ; Y_{2}\right)-I(U ; V \mid W) \\
2 R_{0}+R_{1}+R_{2} & <I\left(W, V ; Y_{1}\right)+I\left(W, U ; Y_{2}\right)-I(U ; V \mid W) \tag{12}
\end{align*}
$$

for some $\operatorname{pmf} p(w, u, v)$ and function $x(w, u, v)$.
Note that, Marton's region can be larger than the Cover-van der Meulen inner bound since the set of distribution on $(W, U, V)$ is larger and the negative term $I(U ; V \mid W)$ drops out of the second and third bounds in (11) if we restrict the set of distributions to the form $p(w) p(u \mid w) p(v \mid w)$.

The achievability of the Marton inner bound involves a new key idea beyond the proof of the Cover-van der Meulen bound, which is multicoding: Instead of assigning a single codeword to each message, we assign a subcodebook to it from which a codeword is selected for transmission depending on a certain joint typicality condition. This idea was first introduced in 1974 by Kuznetsov and Tsybakov in their paper on computer memory with defects [48]. Multicoding was later used by Gelfand and Pinker [27] and Heegard and El Gamal [36] to generalize the Kuznetsov-Tsybakov result to establish the capacity of the DMC with state known noncausally at the sender.

Figure 4
MIMO BC. The sender $\mathbf{X}$ is a $t$-dimensional vector, the receivers $\mathbf{Y}_{1}$ and $\mathbf{Y}_{2}$ are $r$-dimensional vectors, $G_{1}, G_{2}$ are $r \times t$ channel gain matrices, and $\mathbf{Z}_{1} \sim \mathrm{~N}\left(0, I_{r}\right)$ and $\mathbf{Z}_{2} \sim \mathrm{~N}\left(0, I_{r}\right)$ are the additive noise vectors.

Using this result, Costa in [10] showed that the capacity of the Gaussian channel with additive Gaussian state known noncausally is the same as for the case with no state at all!

Follow-on work: Marton's original proof established achievability for each corner point of the region, then used time sharing to establish achievability for the entire region. Shortly after Marton's result, El Gamal and van der Meulen [22] provided a simple proof that directly establishes achievability for any point in the inner bound without the need for time sharing that we sketch here. Randomly generate a codebook $\left\{w^{n}\left(m_{0}, m_{01}, m_{02}\right)\right\}$, and for each $w^{n}\left(m_{0}, m_{01}, m_{02}\right)$, randomly and conditionally independently generate subcodebooks $\left\{u^{n}\left(m_{0}, m_{01}, m_{02}, l_{22}\right): l_{22} \in[1:\right.$ $\left.\left.r_{22}\right]\right\}$ and $\left\{v^{n}\left(m_{0}, m_{01}, m_{02}, l_{11}\right): l_{11} \in\left[1: r_{11}\right]\right\}$ according to $p(u \mid w)$ and $p(v \mid w)$, respectively. To send $\left(m_{0}, m_{1}, m_{2}\right)$, find a jointly typical triple $\left(w^{n}\left(m_{0}, m_{01}, m_{02}\right), u^{n}\left(m_{0}, m_{01}\right.\right.$, $\left.\left.m_{02}, l_{22}\right), v^{n}\left(m_{0}, m_{01}, m_{02}, l_{11}\right)\right)$ with respect to to $p(w, u, v)$. The conditions for the existence of such a triple are provided by the mutual covering lemma [21]. Note that, although the messages $\left(M_{0}, M_{1}, M_{2}\right)$ are independent of each other, their codewords are generated according to the given $p(w, u, v)$. The details of the proof use standard arguments [22].

El Gamal and Cover [20] subsequently used this mutual covering lemma to establish an inner bound on the rate region of the multiple description coding setting.

Multi-input multi-output (MIMO) BC: One of the most important follow-on results to Marton's inner bound is proving that it is tight for the MIMO (or vector Gaussian) BC depicted in Figure 4 with average power transmission constraint $\sum_{i=1}^{n} \mathbf{x}^{T}\left(m_{0}, m_{1}, m_{2}, i\right) \mathbf{x}\left(m_{0}, m_{1}, m_{2}, i\right) \leq n P$ for $\left(m_{0}, m_{1}, m_{2}\right) \in\left[1: 2^{n R_{0}}\right] \times\left[1: 2^{n R_{1}}\right] \times\left[1: 2^{n R_{2}}\right]$. The importance of this result stems from its practical significance as a performance limit on communication over a multiple antenna wireless downlink system.

Figure 5
Distributed source coding for computing setup.
computationally intractable. For the very few cases in which simulations were feasible, the two-letter region did not improve upon the single-letter. Second, there is no known single outer bound that subsumes all existing outer bounds on the capacity region of the BC; see, e.g., Gohari and Nair's work [30], which suggests that none of them is tight, and perhaps Marton is tight. One of the few general optimality results of the region is by Nair et al. [63] who showed that in general, the slope of the region at each corner point is tight.

On the negative side, Padakandla and Pradhan [75] showed using a structured coding scheme that a natural extension of Marton's inner bound to three-receiver BC is not tight. This suggests that perhaps structured coding, which was pioneered by Marton as discussed in the following section, could improve upon Marton's inner bound even for two receivers.

## Distributed Coding for Computing

Consider the distributed source coding for computing setup in Figure 5. Let $(X, Y) \sim p(x, y)$ be two discrete memoryless sources (2-DMS) and $z(x, y)$ be a function of $(x, y)$. The source sequences $X^{n}$ and $Y^{n}$ are separately encoded into the indices $M_{j} \in\left[1: 2^{n R_{j}}\right], j=1,2$, respectively. Upon receiving $\left(M_{1}, M_{2}\right)$ the decoder finds the estimate $\hat{Z}^{n}$ of $Z\left(X_{i}, Y_{i}\right), i=$ $1, \ldots, n$. The problem is to find the rate region, which is the closure of the set of rate pairs $\left(R_{1}, R_{2}\right)$ such that the probability of decoding error can be made as small as desired.

For $z(x, y)=(x, y)$, this setting reduces to the distributed source coding problem for which the rate region was established in a pioneering paper on multiuser information theory by Slepian and Wolf [86].

Slepian-Wolf region: The rate region for the distributed source coding of the 2-DMS $(X, Y)$ is the set of rate pairs ( $R_{1}, R_{2}$ ) such that

$$
\begin{align*}
R_{1} & \geq H(X \mid Y) \\
R_{2} & \geq H(Y \mid X) \\
R_{1}+R_{2} & \geq H(X, Y) . \tag{13}
\end{align*}
$$

This result was quite surprising as it showed that the sum rate for optimal distributed source coding is the same as for the centralized case in which $(X, Y)$ are encoded together. In [43], Körner and Marton considered a coding for
distributed computing example in which $X \sim \operatorname{Bern}(0.5)$, and $Y=X+Z \bmod 2$, where $Z \sim \operatorname{Bern}(p), 0<p<0.5$; hence, the function is $Z=X+Y \bmod 2$. The Slepian-Wolf region yields the following inner bound on the rate region for this distributed computing example:

$$
\begin{align*}
R_{1} & >H(p) \\
R_{2} & >H(p) \\
R_{1}+R_{2} & >1+H(p) \tag{14}
\end{align*}
$$

It can also be shown that the following is an outer bound on the rate region for this example:

$$
\begin{equation*}
R_{1} \geq H(p), \quad R_{2} \geq H(p) \tag{15}
\end{equation*}
$$

Note that this region can be much larger than (14). Körner and Marton showed using random linear codes that this outer bound is optimal. The idea is to randomly generate a $n R \times n$ binary matrix $A$ and use it to encode $X^{n}$ and $Y^{n}$ into the binary $n R$-sequences $M_{1}=A X^{n}$ and $M_{2}=A Y^{n}$, respectively. The decoder then adds these two sequences modulo two to obtain $A Z^{n}$. By Shannon's asymptotically lossless source coding theorem for a binary iid source via linear codes [21], it can be readily shown that this scheme succeeds provided $R>H(p)+\epsilon$, which yields the region in (15).

Follow-on work: Orlitsky and Roche [72] provided the following refined outer bound on the rate region of the distributed computing setting:

$$
R_{1} \geq H_{\mathcal{G}_{1}}(X \mid Y), \quad R_{2} \geq H_{\mathcal{G}_{2}}(Y \mid X)
$$

where, $H_{\mathcal{G}}$ refers to the graph entropy, $\mathcal{G}_{1}$ and $\mathcal{G}_{2}$ are the characteristic graphs for $(X, Y, z)$ and ( $Y, X, z$ ), respectively, as defined in Orlitsky and Roche's work [72], and $H_{\mathcal{G}_{1}}(X \mid Y) \leq H(X \mid Y)$ and $H_{\mathcal{G}_{2}}(Y \mid X) \leq H(Y \mid X)$.

The realization that higher rates can be achieved in multiuser communication settings using structured rather than "unstructured" random codes led to several follow-on works to Körner and Marton [43]. Krithivasan and Pradhan established a rate region for distributed compression of linear functions of correlated Gaussian sources [45] and of DMS [44]. In channel coding settings, the usefulness of structured codes is apparent through the lens of linear network coding in which intermediate nodes forward linear combinations of messages. Nazer and Gastpar showed that noisy MAC could be used for distributed, reliable computation of linear functions first for the modulo-adder case via linear codes [70] and later for the Gaussian case via nested lattice codes [71]. In addition, Wilson et al. [96] utilized structured codes for bidirectional relaying, Bresler et al. [8] used them to approximate the capacity region of the many-to-one Gaussian interference channel to within a constant gap, and Philosof et al. used them to enable distributed dirty paper coding [77].

While the abovementioned efforts focused on particular source and channel models for which structured codes are especially well suited, a series of recent papers by Padakandla and Pradhan [75], [76] as well as Lim et al. [50] showed how multicoding can extend these results to more general settings.

## Acknowledgments

The authors would like to thank Michael Gastpar, John Gill, Amin Gohari, Young-Han Kim, Tamás Linder, Chandra Nair, and Ayfer Özgür for their valuable contributions to this article.
